

# **ABSTRACT**

This report researches **gyroids' stress and strain behaviour in the shank of quadrupled robotic legs**. Mass reduction is an excellent way to have reasonable control in robotics as it also reduces the inertia of legs. In this report, I tried to reduce mass by using biomimicry and inserting some nature-inspired structures in the central portion of the shank and covering it with thick plates. Butterfly wings have inspired this design **with beams enclosing gyroids**. Butterfly wings require a high strength-to-weight ratio, so we decided to mimic them.

## **INTRODUCTION**

Mass reduction in high payload-carrying robotics is always an area of concern. The robot must be robust enough to carry a high payload. But this led to an undesirable increment in mass due to increased inertia, making robotic legs unstable and challenging to control. So we have to find a way to increase its strength but reduce mass, in a way increase strength to weight ratio.

One quite popular way to do this is topology optimization. Topology optimization is a mathematical method that optimizes material layout within a given design space for a given set of loads, boundary conditions, and constraints to maximize the system's performance. Nowadays, this can be done using software like Solidworks and Ansys. Another way is to use topology-optimized structures like gyroids, Schwartz. In this report, I tried to use gyroids to experiment with increasing strength to weight ratio.

### **What are gyroids?**

Gyroid structures are complex, three-dimensional structures characterized by repeating patterns of interconnected, curved surfaces. They are often found in nature [\[1\]](#), such as in certain corals and butterfly wings [\[2\]](#), but can be created synthetically using 3D printing or other fabrication methods.

The gyroid structure is unique because it is a triply periodic minimal surface (TPMS). It has a relatively higher surface area for a given volume and can be repeated infinitely in three dimensions without intersecting itself. This makes it an ideal structure for various applications, from materials science and engineering to architecture and design. One major example of their application is in the shock absorber of UAV Lockheed Martin [\[3\]](#). Gyroids can also be used for robotic applications like drone arms [\[7\]](#), which have significant torsional and bending loads due to thrust forces at their ends.

One notable feature of gyroid structures is their surface area-to-volume ratio, making them useful for energy storage, filtration, and catalysis applications. In addition, their interconnected pore network provides a high degree of structural stability and mechanical strength, making them ideal for lightweight and strong materials.

My finding through this experiment indicates that adding the shank's internal mesh helps decrease mass by 30 g while increasing strength in torsional loads. This experiment tests the novelty of the application of gyroids in various fields. Nowadays where it is widely used in aerial robotics. In on-ground robotics, the application of gyroids is still less researched and

implemented due to its complexity in manufacturing. Still, we tested it for on-ground robotics in quadrupled robotic legs.

### The cellular structure of the gyroid

**Fig 1- Fig 2: Design parameters of gyroid cell and CAD model of the gyroid cell**[\[4\]](#)

The principal design parameters in the gyroid cell are **unit cell size (L)** and **thickness (T)**. The thickness of the gyroid cell is the main parameter that provides strength to the gyroid cell. In other words, **the strength of the gyroid cell is directly proportional to the thickness of the gyroid cell.** [\[2\]](#)

In the subsequent sections, I have discussed all the design, simulation, and observations in detail.

The structure of this report is as follows: -

- **Section 1:** - Design of original shank and modifications done to it
- **Section 2:** - Boundary conditions and loads used in Ansys for simulation
- **Section 3:** - Stress-strain results from Ansys simulation
- **Section 4:** - Accuracy and convergence of results
- **Section 5:** - Observations and discussion about the trend of results
- **Section 6:** - Conclusion and future scope of this Idea

## Section 1: Design of original shank and modifications done in it

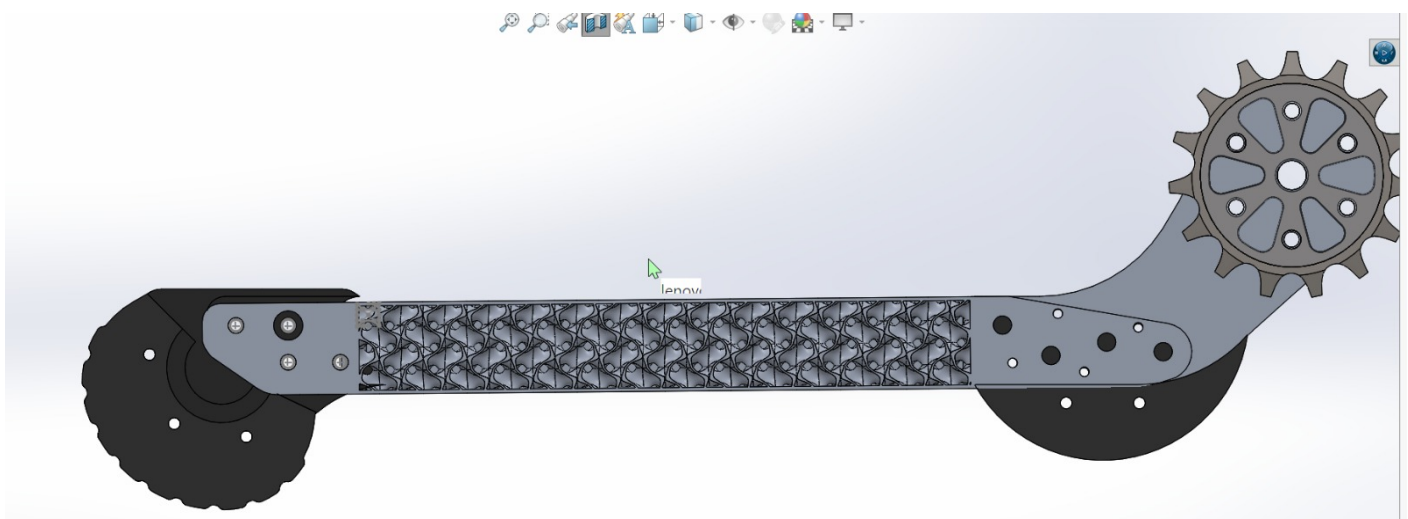

**Fig 3: Shank with the initial central part**

**Fig 5: The initial central part**

Initially, the original shank had a solid I-beam structure in its center, solid from the inside. It is **made of aluminum 6061 alloy weighted 180g**. We optimize shank weight by doing design modifications in this central portion by inserting gyroids. This **reduced its mass by 30 g**.

**Fig 6: Section view of the shank with the central portion filled with gyroids.**

**Fig 7: Section view of the central portion filled with gyroids.**

While in the center, there are gyroid cells of 0.5 mm thickness, in its outer portion, there are 1mm thick plates on all sides. I have finalized this thickness because increasing more than these values will increase weight while decreasing it will lead to high stresses. So we are transmitting all the load outside while making some cavities in the central portion to reduce weight. This is exactly how butterfly wings have been made, which gives them strength and makes them lightweight at the same time.

In the initial design of the gyroid shank, there were sharp edges where high-stress concentrations were coming, so fillets and chamfers were added in those parts, as seen in Fig 8.

**Fig 8: Fillets and chamfers in gyroid shank design**

Those portions in Fig 8 which have been kept solid from the inside are critical areas where nut bolts will be fitted.

## **Section 2:- Design models, Boundary conditions, and loads used in Ansys for simulation**

Ansys software have been used to compare the strength between the original shank and gyroid-filled central parts. This structural analysis uses Ansys mechanical, which works on FEA ( Finite Element Analysis ). I have used the cartesian mesh method, and to check the accuracy of results have done an analysis using three different element sizes of 1 mm, 0.5 mm, and 0.4 mm. I have analyzed one original and three design models.

- The original shank's central portion is an I-beam type structure, completely solid from the inside.

**Fig 10: Original shank**

- In gyroid shank\_v6, there are no fillets and sharp edges at the intersection of gyroid filled central part with the critical portion of bolts.

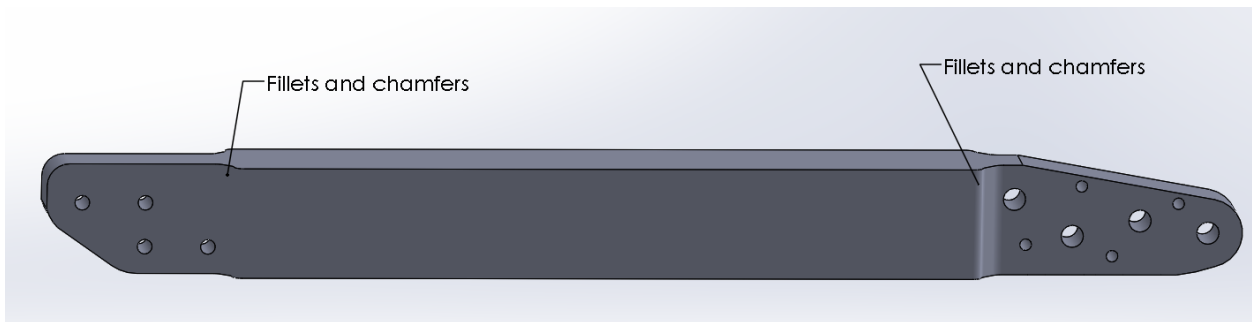

**Fig 11: Gyroid shank\_v6**

- In gyroid shank\_v13, fillets and chamfers are added on the upper edges of the intersection of gyroid filled central part with the critical portion of bolts. These fillets and chamfers are added just on the above edges because those are the areas where there is quite a lot of stress concentration.

**Fig 12: Gyroid shank v13**

- In gyroid shank\_v18, fillets and chamfers are added on both lower and upper intersection edges. Also, there are sharp edges inside, so fillets are added there also to minimize stress concentrations.

**Fig 13: Gyroid shank v18**

I do six Ansys mechanical simulations on each model by applying **forces of 400 N** and **moments of 200 N.m** in all three directions separately. I fixed the holes in the upper portion while applying forces and moments on the opposite bottom part, as depicted in Fig 10 - Fig15.

**Fig 14 - Fig 16: Forces loading condition in x,y, and z directions**

**Fig 17 - Fig 19: Moment loading condition in x,y, and z directions**

### **Section 3: - Stress-strain results from Ansys simulation**

## Section 4: - Accuracy and convergence of results

For checking of accuracy and convergence of results, we will be looking at **Max Total Deformation** [5]. The reason for using these two parameters only is that the other parameters will be affected by stress singularities, which will give inaccurate error percentages.

A **stress singularity**[6] is a mesh point where the stress does not converge towards a specific value. As we keep refinement the mesh, the stress at this point keeps increasing, and increasing, and increasing... Theoretically, the stress at the singularity is infinite. However, **these stress singularities do not affect deformations because they are calculated directly and thus have no relation to stresses, unlike strain and Factor Of Safety (FOS).**

For **checking convergence**, we will be using the following formula[5]:-

$$\text{Error} = 100 * |(\phi_{i+1} - \phi_i) / \phi_i| < E$$

**Where** :  $\phi$  : Max Total Deformation

E: User defined accuracy

i: Refinement iteration

We will be keeping **E = 5%**, and if we get error less than 5%, then we can say that the results are accurate and the meshes are converging.

## **Section 5: - Observations and discussion about the trend of results**

- For the original shank, the results are **converging from 1 mm mesh to 0.5 mm mesh and from 0.5 mm mesh to 0.4 mm mesh** as in both of the cases the error is less than 5% **as calculated in section 4.**
- For all gyroid shanks, the results **converge from 0.5 mm mesh to 0.4 mm mesh** showing error less than 5%, but **they do not converge with 1 mm mesh** which shows significant large errors greater than 5%.
- Stress singularity trend can be seen as we refine mesh more and more; the average equivalent stresses also increase.
- The gyroid shank\_v13 and gyroid shank\_v18 are showing better results in all forces and moments than gyroid shank\_v6. So we can say that adding fillets and chamfers at sharp edges where the structure transitions from gyroid to solid improves stress distribution and deformations.
- Compared to the original shank, gyroid shanks v13 and v18 show better Fx, Fy, Mx, and Mz results when considering total deformations.
- In Mz, the results between gyroid shanks and original shanks in all three meshes have a huge difference. So we may conclude that gyroids help manage torsional loads better than the solid beam structure of the original shank.
- Although there is inaccuracy in stress and strain results due to stress singularities , still, according to St. Venant's Principle [\[5\]](#), it doesn't mean that stresses in every part will be incorrect. That is why average stresses and average strains have been considered in the results.
- A general conclusion can be made that in linear forces, although the original shank shows better results, there is still not quite a difference between its strength and the strength of gyroid shanks. While applying moments, especially Mz, the gyroid shank shows better results than the original one with a significant difference.
- Gyroid shank\_v18 shows improvement in max total deformation by 5.3% compared to gyroid shank\_v13 while applying Mx . Thus, we can conclude that adding fillets at the outside and inner portion of the central part and all intersections with the solid part has improved the performance while reducing the error of stress singularity a little bit.
- Decreasing gyroid thickness to 0.25mm will decrease weight by 15 grams, and reducing wall thickness to 0.75mm will decrease weight by 10 grams. But in both cases, the strength will also get reduced further.

## **Section 6: - Conclusion and future scope of this Idea**

The central part made of gyroids though reduces weight by 30g, but it will have greater manufacturing complexity and will require greater cost than the original one. Also, there is not a significant difference in strength between the two parts other than Mz, and in the real world, there is very less magnitude of Mz, which will act on the shank of quadrupled robotic leg. So considering all these factors, it has been decided not to bring this design into development yet.

Considering how the gyroids manage torsional loads, it may be applied to other links of the robotic leg, like the thigh and torso, which face significant torsional loads, unlike the shank. To make thigh and torso lightweight we can use sandwich structures but this structure is weak against torsional loads, hence we can use the gyroid's cellular structure here to manage those loads. Also, the scope of using graded gyroids instead of uniform gyroids exists[8]. Graded gyroids are those which have variable cell sizes of gyroids. They have better energy absorption capacity than uniform ones, which is quite interesting. Hence quite a discovery and applications have recently begun to unlock the benefits this structure can provide.
